It said just that, which is vague. Only 15% of food came from the bottom. Which I would guess means that he was distinguishing the bottom from the drift. I.e. trout rarely root around for insects or eggs or what have you on the stream bed. Which makes sense if you watch a trout eat. They will be suspended a few inches off the bottom and move up or down and side to side in varying degrees to feed.

Here's my favorite nugget from the study: This researcher, who watched a protected section of stream from a blind with polarized binoculars, said that trout were observed to feed up to 300 times per minute in shallow water in bright sunlight on the hottest day in August.
