There are many remote streams that hold brookies that have never been stocked and aren't physically connected to any stocked streams that I am aware of. How did these brookies get there? Did birds ingest fertilized eggs from descendents at other streams and poop these eggs into these streams and they actually hatched and naturally populated the stream?

Using your own argument I would say there is no proof that all "native" brookies are the descendents of hatchery fish so therefore they must be native.

BTW, there is documented proof (except the PFBC won't admit it) that the strain of brookies on Big Spring Creek up until the mid 70's was a native strain of brookies unique to Big Spring. Of course the PFBC wiped out this strain with operation of the major hatchery.
